3 Introduction

Field-Programmable Gate Arrays (FPGAs) have witnessed rapid growth in capacity and versatility, driving significant advances in computer-aided design (CAD) and electronic design automation (EDA) methodologies. Since the early-to-mid 2000s, the stagnation of single-processor performance relative to the rapid increase in integrated circuit sizes has led to a design productivity gap, where the computational effort for designing complex chips continues to rise. In FPGA CAD flows—which traditionally encompass logic synthesis, placement, routing, and bitstream generation—the placement stage has emerged as one of the most time-consuming processes. Inefficiencies in placement not only extend design times from hours to days, thereby elevating cost and reducing engineering productivity, but also limit the broader adoption of FPGAs by software engineers who expect compile times akin to those of conventional software compilers.

For these reasons, FPGA placement remains a critical research effort even today. In this paper, we study and implement established placement methods by leveraging RapidWright, which is a semi-open-source API that offers backend access to Xilinx’s industry-standard FPGA environment, Vivado. We implement multiple variations of simulated annealing placers for Xilinx’s 7-series FPGAs, with an emphasis on minimizing total wirelength while mitigating runtime. Our implementation is organized into three consecutive substages. The **prepacking** stage involves traversing a raw EDIF netlist to identify

recurring cell patterns—such as CARRY chains, DSP cascades, and LUT-FF pairs—that are critical for efficient mapping and legalization. In the subsequent **packing** stage, these identified patterns, along with any remaining loose cells, are consolidated into SiteInst objects that encapsulate the FPGA’s discrete resource constraints and architectural nuances. Finally, the **placement** stage employs a simulated annealing (SA) algorithm to optimally assign SiteInst objects to physical sites, aiming to minimize total wirelength while adhering to the constraints of the 7-series architecture.

Simulated annealing iteratively swaps placement objects guided by a cost function that decides which swaps should be accepted or rejected. Hill climbing is permitted by occasionally accepting moves that increase cost, in hope that such swaps may later lead to a better final solution. SA remains a popular approach in FPGA placement research due to its simplicity and robustness in handling the discrete architectural constraints of FPGA devices. While SA yields surprisingly good results given relatively simple rules, it is ultimately a heuristic and stochastic approach that explores the vast placement space by making random moves. Most of these moves will be rejected, meaning that SA must run many iterations, usually hundreds to thousands, to arrive at a desirable solution.

In the ASIC domain, where placers must handle designs with millions of cells, the SA approach has largely been abandoned in favor of analytical techniques, owing to SA’s runtime and poor scalability. Modern FPGA placers have also followed suit, as new legalization strategies allow FPGA placers to leverage traditionally ASIC placement algorithms and adapt them to the discrete constraints of FPGA architectures. While this paper does not present a working analytical placer, it will explore ways to build upon our existing infrastructure (prepacker and packer) to replace SA with AP.

4 A Brief History on FPGA Architecture

Before any work can begin on a placer, it is necessary to understand both the objects to be placed and the medium in which they are placed.

Here we will briefly outline the evolution of configurable logic architecture as well as the FPGA design flow. However, readers who are already familiar with basic FPGA architecture and design flow may skip to the next section on Xilinx 7-Series Architecture. Configurable logic devices have undergone significant evolution over the past four decades. The journey began with the Programmable Logic Array (PLA) in the early 1970s. The PLA implemented output logic using a programmable-OR and programmable-AND plane that formed a sum-of-products equation for each output through programmable fuses. Around the same time, the Programmable Array Logic (PAL) was introduced. The PAL simplified the PLA by fixing the OR gates, resulting in a fixed-OR, programmable-AND design, which sacrificed some logic flexibility to simplify

Figure 2: CPLD architecture with 4 CLBs (PAL-like blocks)

Figure 3: Homogenous island-style FPGA architecture with 16 CLBs in a grid

its manufacture.

Later in the same decade came the Complex Programmable Logic Device (CPLD), which took the form of an array of Configurable Logic Blocks (CLBs). These CLBs were typically modified PAL blocks that included the PAL itself along with macrocells such as flip-flops, multiplexers, and tri-state buffers. The CPLD functioned as an array of PALs connected by a programmable switch matrix and could be programmed using a hardware description language (HDL) like VHDL.

The mid-1980s saw the introduction of the homogeneous FPGA, which was built as a grid of CLBs. Rather than using a central programmable switch matrix as in CPLDs, FPGAs adopted an island style architecture in which each CLB is surrounded on all sides by programmable routing resources. The first commercially viable FPGA, produced by Xilinx in 1984, featured 16 CLBs arranged in a 4x4 grid. As FPGA tech-

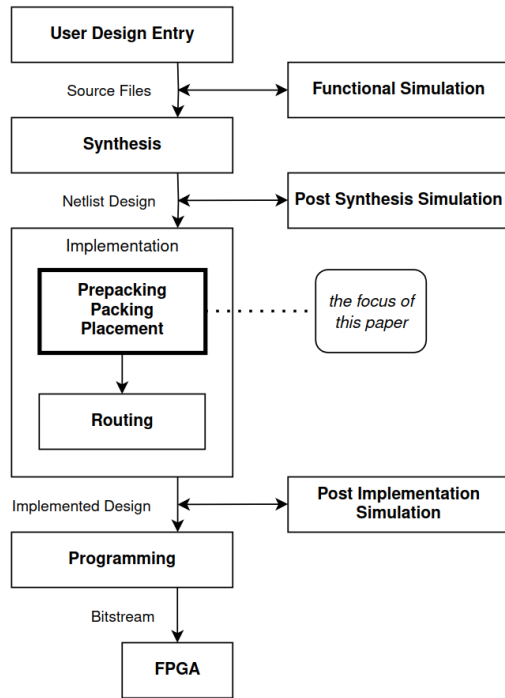

Figure 4: A typical FPGA design and verification flow

nology advanced, CLBs were redesigned to use lookup tables (LUTs) instead of PAL arrays for greater logic density. The capacity of an FPGA was often measured by how many logical elements or CLBs it offered, which grew from hundreds to thousands and now to hundreds of thousands of CLBs.

This brings us to modern day FPGA architectures. To meet the needs of increasingly complex designs, FPGA vendors introduced heterogeneous FPGAs. In these devices, hard macros such as Block RAM (BRAM) and Digital Signal Processing (DSP) slices are integrated into the programmable logic fabric along with CLBs. This design enables the direct instantiation of common subsystems like memories and multipliers, without having to implement them solely with CLBs. Major vendors such as Xilinx and Altera now employ heterogeneous island-style architectures in their devices. As designs become increasingly large and complex, FPGAs become increasingly heterogeneous as they incorporate a wider variety of hard macros into the fabric.

5 The FPGA Design Flow and Toolchain

Figure 4 shows a typical FPGA design and verification flow. The FPGA design flow takes a high-level digital design written in an HDL and gener-

ates a configuration file that programs the physical FPGA.

The process begins with **design entry**, where an engineer describes the functionality of their circuit using a hardware description language (HDL) such as Verilog or VHDL. This description abstracts away details of the physical hardware while defining the logic and behavior of the design.

Next, the **synthesis** tool interprets the HDL code and generates a netlist that represents the design in terms of basic logic elements, such as lookup tables (LUTs) and flip flops. During this stage, substages like instantiation, substitution, inference, optimization, and technology mapping are applied to map the user design to a particular FPGA architecture.

After synthesis, the **placement** tool assigns each logic element in the netlist a specific location within the FPGA’s fabric. This stage can include substages of prepacking, packing, global placement, legalization, and detailed placement. The objective is to place the logical cell instances of the netlist onto physical BELs on the device in a way that minimizes delay, satisfies design constraints, and simplifies routing.

Following placement, the **routing** tool connects the placed elements by assigning physical wiring resources to the nets in the netlist. The router determines their paths through the programmable interconnect network while attempting to meet timing and performance constraints.

Placement and routing are generally referred to together as the **implementation** stage, as both stages are interdependent and must adhere to the constraints of the same device. State of the art (SOTA) tools will perform routing-aware placement for greater optimization.

The final stage is the **bitstream** generation, where a vendor-specific programming tool produces a configuration file or bitstream that programs the physical FPGA device. The bitstream specifies the state of every configurable element—logic blocks, routing switches, and hard macros—ensuring the FPGA implements the user’s design.

Parallel to this entire design flow are simulators for which the user can write testbenches to verify their design at different stages of implementation. Xilinx’s Vivado, for example, provides functional simulation, post-implementation simulation, and post-implementation timing simulation.

This integrated toolchain, whether provided by FPGA vendors or open source communities, facilitates the transformation from an abstract HDL description to a functioning hardware configuration.

6 Xilinx 7-Series Architecture

Xilinx introduced the 7-Series architecture in 2010 which followed the heterogeneous island-style architecture described previously. Then in 2013 Xilinx unveiled Ultrascale architecture which kept the same heterogeneous island-style architecture but made several optimizations over the 7-Series architecture. Although the latest FPGAs follow the Ultrascale architecture, this paper focuses on the 7-Series FPGAs due to their greater accessibility for beginner users and compatibility with open source tooling.

Figure 5 illustrates the architectural hierarchy of an Ultrascale Xilinx FPGA. The architecture hierarchy is the same for the 7-Series devices. The only difference between Ultrascale and 7-Series is simply the design of the CLBs (Sites and BELs) themselves. At its most basic level, an FPGA is a vast physical array of replicated atomic components known as Basic Elements of Logic (BELs). These BELs, which include LUTs, FFs, BRAMs, DSPs, and programmable interconnects, form the fundamental building blocks for custom digital circuit implementations on FPGAs.

The Xilinx architectural hierarchy organizes these BELs into increasingly abstract structures. **BELs** are packaged into **Sites**, which are then embedded into **Tiles**, which are subsequently consolidated into **Clock Regions**. In high-end Xilinx devices, Clock Regions may be further consolidated into **Super Logic Regions** (SLRs). However, for the scope of this paper, we focus on Xilinx devices that have only a single SLR.

7 RapidWright API

We use the RapidWright API to implement a custom placer for Xilinx 7-Series FPGAs. RapidWright is an open source Java framework that enables netlist implementation manipulation for modern Xilinx FPGAs. Figure 6 shows how the API can take design checkpoints in the form of .dcp files generated at any stage of the design implementation, allow the user to make custom optimizations, and reintegrate it back into the design flow. This allows the user to substitute any stage in the default FPGA design flow offered by Vivado with user-defined optimizations and implementations to meet complex design requirements. There are three packages of objects that are most relevant to building our placer: the edif package, design package, and device package. RapidWright reads in a post-synthesis design checkpoint and allows us to traverse the netlist's logical EDIFCells through various func-

tion calls. For each EDIFCell object in the netlist, we create a Cell design object, which we then place onto physical device BEL object. CellPins and Nets are automatically generated from EDIFHierPortInst and EDIFHierNet upon the Cell's creation from an EDIFHierCellInst.

These three steps correspond to our placement substages of PrePacking, Packing, and Placement, respectively. Figure ?? illustrates the flow between these three substages in relation to the RapidWright object classes.

For a complete understanding of the RapidWright packages, please refer to the short API Overview https://www.rapidwright.io/docs/RapidWright_Overview.html. Listed below are the most relevant objects to our placer and a short description.

7.1 EDIF Objects

- EDIFNetlist
- EDIFHierNet
- EDIFHierCellInst
- EDIFHierPortInst

7.2 Design Objects

- Netlist
- Net
- Cell
- CellPin
- SiteInst
- SitePinInst

7.3 Device Objects

- BEL
- PIP (programmable interconnect point)
- Site
- SitePin
- Tile
- ClockRegion

In Vivado, all designs post synthesis have a logical netlist that can be exported as an Electronic Design Interchange Format (EDIF) file or within a .dcp checkpoint file. This is the result of the synthesis tool parsing the raw Verilog source

Figure 5: Architecture Hierarchy of a Xilinx FPGA (Ultrascale)

Figure 6: Showing how RapidWright can take a design checkpoint at different stages of the Vivado toolchain, make customizations, then feed it back into the toolchain.

files, inferring logical behavior, and instantiating primitive cells to emulate the desired logical behavior. The final stage is often referred to as "technology mapping", as the primitive cells are specific to the FPGA architecture and consequently the FPGA manufacturer.

In its current state, RapidWright has several SA-based "BlockPlacers", a general Router, but no general Placer. The BlockPlacer takes multiple pre-implemented designs (that is, designs that have been placed and routed), and instantiates them as hard macros in the form of ModuleInsts. ModuleInsts are a collection of SiteInsts whose positional relationship to each other are fixed. The BlockPlacer takes these hard ModuleInsts and performs simulated annealing on them to find an optimal placement. The Router takes the placed design and routes the nets onto the device wires and programmable interconnects.

To fill this gap, we attempt to build a general Placer that can take a raw EDIF netlist and create a placed design. As mentioned before, our placer will be divided into three substages: prepacking, packing, and placement. We use this API to implement a crude general placer, in our case, a simulated annealer. (Show what parts of the FPGA toolchain that RapidWright already has and how our placer fits into that toolchain).

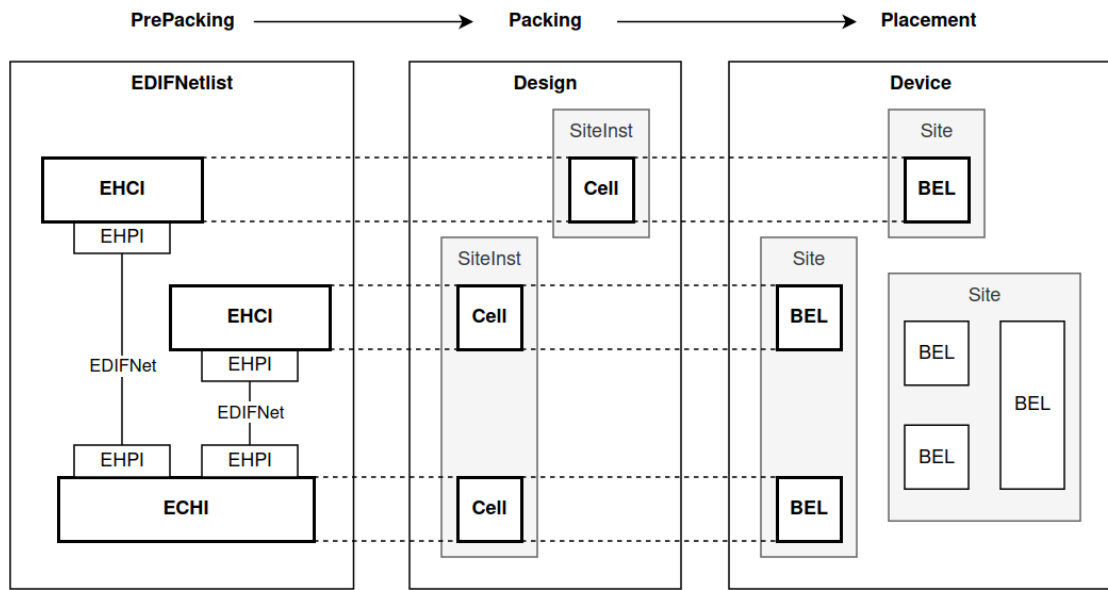

Figure 7: The placement flow illustrating PrePacking into Packing into Placement for a logical netlist with 3 EDIF cells. EHCI is short for EDIFHierCellInst. EHPI is short for EDIFHierPortInst.

8 Placement Implementation

(Describe the algorithm, then in context of 7-Series architecture).

8.1 PrePacking

In the prepacking stage, we traverse the raw EDIF Netlist to identify recurring cell patterns. In particular, we will specifically look for CARRY chains, DSP cascades, and LUT-FF pairs as these patterns are most prevalent in all FPGA designs.

8.2 CARRY Chains

Each SLICE Site contains one CARRY4 BEL. Each CLB Tile contains two SLICE Sites. CARRY chains span vertically across multiple SLICE Sites/Tiles. (Show picture)

8.3 DSP Cascades

Each DSP Site contains one DSP BEL. Each DSP Tile contains two DSP Sites. DSP chains can span vertically across multiple DSP Sites/Tiles.

8.4 LUT-FF Pairs

Identify unique CE-SR net pairs. All FF cells in a Site must share the same CE and SR nets.

8.5 Packing

In the packing stage, we take the identified cell clusters and pack them into SiteInst Design objects which target the Device Site objects.

8.6 CLB Sites

Can support LUT-FF pairs, loose LUTs, loose FFs, CARRY chains. Each SLICE has 8 "lanes" of LUT-FFs. 4 LUT5s and 4 LUT6s. 8 FFs. For SLICEMs, LUT6s can be configured as shallow 32-bit LUTRAMs or "RAMS32".

8.7 Placement

Create BEL "fields": CLB, DSP, CLB and DSP Chains, RAMs

8.8 Detailed Placement

9 Analytical Placement

Introduce placement with legalization methods. Many AP approaches use a Global placement, Legalization, then Detailed placement approach. Our SA only considers legal moves via book-keeping structures, so it has no concept of global placement or legalization. It is a detailed placement only approach.

- Talk about HeAP as an example.
- Global Placement, Legalization, then Detailed Placement approach.
- Global placement using the Bound2Bound net model from SimPL.
- Legalization Step 1:
Find an area of the device that is overutilized (illegal) for which the blocks contained within must spread to a larger area.

Figure 10: A Carry Chain of length 6 spanning 6 Tiles. On the left, the cell-only representation. On the right, cells with routing representation.

To obtain this overutilized area, adjacent locations (Sites, Tiles, etc.) on the device that are occupied by more than one block (SiteInst, ModuleInst, etc.) are repeatedly clustered together, until all clusters are bordered on all sides by non-overutilized locations.

Then, the area (?) is expanded in both the x and y dimensions (?) until it is large enough to accommodate all blocks contained within. Specifically, the area is expanded until its "occupance" O_A divided by its "capacity" C_A is less than a maximum "utilization factor" β , where β is less than or equal to 1. HeAP uses 0.9.

- Legalization Step 2:

Two cuts are generated: a "source cut" and a "target cut".

The source cut pertains to the blocks being placed (SiteInsts in home buffer).

The target cut pertains to the area into which the blocks are placed (away buffer).

The source cut splits the blocks into 2 partitions, while the target cut splits the area into 2 sub-areas, into which the blocks in each partition are spread.

Two objectives are minimized during this process: The imbalance between the number of blocks in each partition, and the difference in the utilization of each sub-area.

Utilization defined as the occupancy divided by the capacity of the sub-area.

$$U_{sub-area} = \frac{O_{sub-area}}{C_{sub-area}}$$

To generate the source cut, the cells are first sorted by their x or y location, depending on the orientation of the desired cut.

Once the cells are sorted, the source cut generation is akin to choosing a pivot in a sorted list, where all blocks to the left of the pivot are assigned to the left/bottom partition and all blocks to the right of the pivot are assigned to the right/top partition.

The target cut is an x or y cut of the area such that all blocks in each partition fit in their respective sub-areas, and such that $|U_{sub-area_1} - U_{sub-area_2}|$ is minimized.
